Abstract

We characterize solutions for two-sided matching, both in the transferable- and in the nontransferable-utility frameworks, using a cardinal formulation. Our approach makes the comparison of the matching models with and without transfers particularly transparent. We introduce the concept of a no-trade matching to study the role of transfers in matching. A no-trade matching is one in which the availability of transfers do not affect the outcome.

1 Introduction

We explore the role of transfers and cardinal utility in matching markets. Economists regularly use one- and two-sided models, with and without transfers. For example auctions allow for monetary transfers among the agents, while models of marriage, organ donation and “housing” exchanges do not. There are two-sided matching models of the labor market without transfers, such as the market for medical interns in the US; and traditional models of the labor market where salaries, and therefore transfers, are allowed. We seek to understand how and why transfers matter in markets for discrete goods.

The question is interesting to us as theorists, but it also matters greatly for one of the most important applications of matching markets, namely the medical interns market. In the market for medical interns in the US (see Roth (1984a), Roth and Sotomayor (1990), and Roth (2002)), hospitals match with applicants using a centralized clearinghouse that implements a stable matching. We always think of this market as one *without* transfers, because salaries are fixed first, before the matching is established. So at the stage in which the parties “bargain” over who is to be matched to whom, salaries are already fixed, and thus there are no transfers.

There is a priori no reason for things to be this way. Hospitals and interns could instead bargain over salaries and employment at the same time. This is arguably the normal state of affairs in most other labor markets; and it has been specifically advocated for the medical interns market in the US (see Crawford (2008)). It is therefore important to understand the impact of disallowing transfers in a matching market. Our paper is a first step towards understanding this problem.

In a two-sided matching market—for our purposes, in the Gale-Shapley marriage market—this impact is important. We consider two canonical models: the marriage market without transfers (the NTU model) and the marriage market with transfers (the TU model, also called the assignment game).

There are Pareto efficient, and even stable, matchings in the NTU model that a utilitarian social planner would never choose, regardless of how she weights agents’ utilities. A utilitarian social planner has implicitly access to transfers. The gap between (utilitarian) efficiency with transfers and without them can be arbitrarily large. From the viewpoint of the recent literature in computer science on the “price of anarchy” (see e.g. Roughgarden (2005)), the “price of stability” can be arbitrarily bad, and grow exponentially with the size of the market (see our Proposition 16).

We present results characterizing Pareto efficiency and the role of transfers in marriage models. Ex-ante Pareto optimality in the model with transfers is characterized by the maximization of the weighted utilitarian sum of utilities, while Pareto optimality when there are no transfers is equivalent to a different maximization problem, one where the weighted sum of “adjusted” utilities are employed. Each of these problems, in turn, have a formulation as a system of linear inequalities. The results follow (perhaps unexpectedly) from Afriat’s theorem in the theory of revealed preference.

In order to explore the role of transfers, we study a special kind of stable matching: A *no-trade matching* in a marriage market is a matching that is not affected by the presence of transfers. Agents are happy remaining matched as specified by the matching, even if transfers are available, and *even though they do not make use of transfers*. Transfers are available, but they are not needed to support the stable matching. There is thus a clear sense in which transfers play no role in a no-trade matching.

The notion of no-trade matching is useful for the following reason. We can think of transfers as making some agents better off at the expense of others. It is then possible to modify a market by choosing a cardinal utility representation of agents preferences with the property that the matching remains stable with and without transfers (Theorem 12). Under certain circumstances, namely when the stable matchings are “isolated,” we can choose a cardinal representation that will work in this way for every stable matching. So under such a cardinal representation of preferences, any stable matching remains stable regardless of the presence of transfers. Finally (Example 14), we cannot replicate the role of transfers by re-weighting agents’ utilities. In general, to instate a no-trade matching, we need the full freedom of choosing alternative cardinal representations.

It is easy to generate examples of stable matchings that cannot be sustained when transfers are allowed, and of stable matchings that can be sustained with transfers (in the sense of being utilitarian-efficient), but where transfers are actually used to sustain stability. We present conditions under which a market has a cardinal utility representation for which stable matchings are no trade matchings.

In sum, the notion of a no-trade matching captures both TU and NTU stability: a no-trade stable matching is also a TU and NTU stable matching. TU stability is, on the other hand, strictly stronger than ex-ante Pareto efficiency, which is strictly stronger than ex-post Pareto efficiency. NTU

stability is strictly stronger than ex-post Pareto efficiency.¹

The model without transfers was introduced by Gale and Shapley (1962). The model with transfers is due to Shapley and Shubik (1971). Kelso and Crawford (1982) extended the models further, and in some sense Kelso and Crawford’s is the first paper to investigate the effects of adding transfers to the Gale-Shapley marriage model. Roth (1984b) and Hatfield and Milgrom (2005) extended the model to allow for more complicated contracts, not only transfers (see Hatfield and Kojima (2010) and Echenique (2012) for a discussion of the added generality of contracts). We are apparently the first to consider the effect of transfers on a given market, with specified cardinal utilities, and the first to study the notion of a no-trade matching.

2 The Marriage Problem

2.1 The model

Let M and W be finite and disjoint sets of, respectively, men and women; $M \cup W$ comprise the *agents* in our model. We can formalize the marriage “market” of M and W in two ways, depending on whether we assume that agents preferences have cardinal content, or that they are purely ordinal. For our results, it will be crucial to keep in mind the difference between the two frameworks.

An *ordinal marriage market* is a tuple (M, W, P) , where P is a *profile*: a list of preferences $>_i$ for every man i and $>_j$ for every woman j . Each $>_i$ is a linear order over $W \cup \emptyset$, and each $>_j$ is a linear order over $M \cup \emptyset$. Here, \emptyset represents the alternative of being unmatched. The weak order associated with $>_s$ is denoted by \geq_s for any $s \in M \cup W$.²

We often specify a preference profile by describing instead utility functions for all the agents. A *cardinal marriage market* is a tuple (M, W, U, V) , where U and V define the agents’ utility functions: $U(i, j)$ (resp. $V(i, j)$) is the amount utility derived by man i (resp. woman j) out of his match with woman j (resp. man i). The utility functions U and V *represent* P if, for

¹TU and NTU stability are not comparable in this sense. Empirically, though, they are comparable, with TU stability having strictly more testable implications than NTU stability (Echenique, Lee, Shum, and Yenmez, 2013).

²A linear order is a binary relation that is complete, transitive and antisymmetric. The weak order \geq_s is defined as $a \geq_s b$ if $a = b$ or if $a >_s b$.

any i

$$U(i, j) > U(i, j') \iff j >_i j'$$

and for any j

$$V(i, j) > V(i', j) \iff i >_j i'.$$

We say that U and V are a *cardinal representation of P* . Clearly, for any cardinal marriage market (M, W, U, V) there is a corresponding ordinal market.

A one-to-one function $\sigma : M \rightarrow W$ is called a *matching*. When $w = \sigma(m)$ we say that m and w are matched, or married, under σ . In our setting, under a given matching, each man or woman is married to one and only one partner of the opposite sex. We shall denote by \mathcal{A} the set of matchings. We shall assume that M and W have the same number of elements, so that \mathcal{A} is non-empty.

Implicit in our definition of matching is that agents are always married: We do not allow for the possibility of singles. The assumption of no-singles is done for economy of exposition, and we do not believe that our results depend on it.

Under our assumptions, we can write $M = \{m_1, \dots, m_n\}$ and $W = \{w_1, \dots, w_n\}$. For notational convenience, we often identify m_i and w_j with the numbers i and j , respectively. So when we write $j = \sigma(i)$ we mean that woman w_j and man m_i are matched under σ .

We shall often fix an arbitrary matching, and without loss of generality let this matching be the *identity matching*, denoted by σ_0 . That is,

$$\sigma_0(i) = i.$$

For a matching σ , let $u_\sigma(i) = U(i, \sigma(i))$ and $v_\sigma(j) = V(\sigma(j), j)$. When $\sigma = \sigma_0$, we shall often omit it as a subscript and just use the notation u and v .

One final concept relates to random matchings. We consider the possibility that matching is chosen according to a lottery: a *fractional matching* is a matrix $\pi = (\pi_{i,j})$ such that $\pi_{ij} \geq 0$ and letting π_{ij} the probability that individuals i and j get matched, the constraints on π are

$$1 = \sum_{i=1}^n \pi_{ij} = \sum_{j=1}^n \pi_{ij},$$

(i.e. π is a *bistochastic matrix*). It is a celebrated result (the Birkhoff von-Neumann Theorem) that such matrices result from a lottery over matchings. Let \mathcal{B} denote the set of all fractional matchings.

2.2 Solution concepts

We describe here some commonly used solution concepts. The first solutions capture the notion of Pareto efficiency. In second place, we turn to notion of core stability for matching markets. For simplicity of exposition, we write these definitions for the specific matching σ_0 . Of course by relabeling we can express the same definitions for an arbitrary matching.

A solution concept singles out certain matchings as immune to certain alternative outcomes that could be better for the agents. If we view such alternatives as arising ex-post, after any uncertainty over which matching arises has been resolved, then we obtain a different solution concept than if we view the alternatives in an ex-ante sense.

2.2.1 NTU Pareto efficiency

Matching $\sigma_0(i) = i$ is *ex-post NTU Pareto efficient* if there is no matching σ that is at least as good as σ_0 for all agents, and strictly better for some agents. That is, such that the inequalities $U(i, \sigma(i)) \geq U(i, i)$ and $V(\sigma^{-1}(j), j) \geq V(j, j)$ simultaneously hold with at least one strict inequality.

In considering alternative matchings, it is easy to see that one can restrict oneself to cycles. The resulting formulation of efficiency is very useful, as it allows us to relate efficiency with standard notions in the literature on revealed preference.

Hence matching $\sigma_0(i) = i$ is ex-post Pareto efficient if and only if for every cycle $i_1, \dots, i_{p+1} = i_1$, inequalities $U(i_k, i_{k+1}) \geq U(i_k, i_k)$ and $V(i_k, i_{k+1}) \geq V(i_k, i_k)$ cannot hold simultaneously unless they all are equalities. In other words:

Observation 1 *Matching $\sigma_0(i) = i$ is ex-post NTU Pareto efficient if for every cycle $i_1, \dots, i_{p+1} = i_1$, and for all k , inequalities*

$$U(i_k, i_{k+1}) \geq U(i_k, i_k) \text{ and } V(i_k, i_{k+1}) \geq V(i_k, i_k),$$

cannot hold simultaneously unless they are all equalities.

In an ex-ante setting, we can think of probabilistic alternatives to σ_0 . As a result, we obtain the notion of ex-ante Pareto efficiency. For matching $\sigma_0(i) = i$ to be *ex-ante Pareto efficient*, we require not only that there is no other matching which is preferred by every individual, but also that there is no lottery over matchings that would be preferred.

Formally: Matching $\sigma_0(i) = i$ is *ex-ante NTU Pareto efficient* if for any $\pi \in \mathcal{B}$, and for all i and j , inequalities

$$\sum_j \pi_{ij} U(i, j) \geq U(i, i) \quad \text{and} \quad \sum_i \pi_{ij} V(i, j) \geq V(j, j)$$

cannot hold simultaneously unless they are all equalities.

Note that the problem of ex-post efficiency is purely ordinal, as ex-post efficiency of some outcome only depends on the rank order preferences, not on the particular cardinal representation of it. In contrast, the problem of ex-ante efficiency is cardinal, as we are adding and comparing utility levels across states of the world.

2.2.2 TU Pareto efficiency

We now assume that utility is transferable across individuals. In this case, a matching is Pareto efficient if no other matching produces a higher welfare, accounted for as the sum of individual cardinal utilities. It is a direct consequence of the Birkhoff-von Neumann theorem that if a fractional matching produces a higher welfare, then some deterministic matching also produces a higher welfare. As a result, the notions of ex-ante and ex-post TU Pareto efficiency coincide, and we do not need to distinguish between them.

Matching $\sigma_0(i) = i$ is *TU Pareto efficient* if there is no matching σ for which

$$\sum_{i=1}^n U(i, \sigma(i)) + V(i, \sigma(i)) > \sum_{i=1}^n U(i, i) + V(i, i).$$

Observation 2 *Matching $\sigma_0(i) = i$ is TU Pareto efficient if for every cycle $i_1, \dots, i_{p+1} = i_1$, and for all k , inequalities*

$$\sum_{k=1}^p U(i_k, i_{k+1}) + V(i_k, i_{k+1}) \geq \sum_{k=1}^p U(i_k, i_k) + V(i_{k+1}, i_{k+1})$$

cannot hold simultaneously unless they are all equalities.

In the previous definitions, transfers are allowed across any individuals. One may have considered the possibility of transfers only between matched individuals. It is however well known since Shapley and Shubik (1971) that this apparently more restrictive setting leads in fact to the same notion of efficiency.

2.2.3 NTU Stability

We now review notions of stability. Instead of focusing on the existence of a matching which would be an improvement for everyone (as in Pareto efficiency), we focus on matchings which would be an improvement for a newly matched pair of man and woman. Thus we obtain two solution concepts, depending on whether we allow for transferable utility.

Our definitions are classical and trace back to Gale and Shapley (1962) and Shapley and Shubik (1971). See Roth and Sotomayor (1990) for an exposition of the relevant theory.

Matching $\sigma_0(i) = i$ is *stable in the nontransferable utility matching market*, or *NTU stable* if there is no “blocking pair” (i, j) , i.e. a pair (i, j) such that $U(i, j) > U(i, i)$ and $V(i, j) > V(j, j)$ simultaneously hold.

Hence, using our assumptions on utility, we obtain the following:

Definition 3 *Matching $\sigma_0(i) = i$ is NTU stable if*

$$\forall i, j : \min(U(i, j) - U(i, i), V(i, j) - V(j, j)) \leq 0.$$

Of course, this notion is an ordinal notion and should not depend on the cardinal representation of men and women’s preferences, only on the underlying ordinal matching market.

2.2.4 TU Stability

Utility is transferable across pair (i, j) if there is the possibility of a utility transfer t (of either sign) from j to i such that the utility of i becomes $U(i, j) + t$, and utility of j becomes $V(i, j) - t$. When we assume that utility is transferable, in contrast, we must allow blocking pairs to use transfers. Then a couple (i, j) can share, using transfers, the “surplus” $U(i, j) + V(i, j)$. Thus we obtain the definition:

Definition 4 Matching $\sigma_0(i) = i$ is TU stable, if there are vectors $\tilde{u}(i)$ and $\tilde{v}(j)$ such that for each i and j ,

$$\tilde{u}(i) + \tilde{v}(j) \geq U(i, j) + V(i, j)$$

with equality for $i = j$.

By a celebrated result of Shapley and Shubik (1971), this notion is equivalent to the notion of TU Pareto efficiency. Note that there may be multiple vectors \tilde{u} and \tilde{v} for the given matching σ_0 .

2.3 No-Trade stability

The notions of TU and NTU stability have been known and studied for a very long time. Here, we seek to better understand the effect that the possibility of transfers has on a matching market. We introduce a solution concept that is meant to relate the two notions.

Note that if matching $\sigma_0(i) = i$ is TU stable, then there are transfers between the matched partners, say from woman i to man i , equal to

$$T_i = \tilde{u}(i) - U(i, i) = V(i, i) - \tilde{v}(i) \tag{2.1}$$

where the payoffs $\tilde{u}(i)$ and $\tilde{v}(j)$ are those of Definition 4. We want to understand the situations when matching $\sigma_0(i) = i$ is TU stable but when no actual transfers are made “in equilibrium.” As a result, the matching σ_0 is NTU stable as well as it is TU stable.

We motivate the notion of a No-Trade matching with an example. We present a matching market with a matching which is both the unique TU stable matching and also the unique NTU stable matching. In order for agents to *accept it*, however, transfers are needed.

Example 5 In this and other examples, we write the payoffs U and V in matrix form. In the matrices, the payoff in row i and column j is the utility $U(i, j)$ for man i in matrix U , and utility $V(i, j)$ for woman j in matrix V .

Consider the following utilities

$$U = \begin{pmatrix} 0 & 2 & 1 \\ 1 & 2 & 0 \\ 1 & 0 & 2 \end{pmatrix}, \quad V = \begin{pmatrix} 2 & 1 & 0 \\ 1 & 2 & 0 \\ 0 & 1 & 2 \end{pmatrix}$$

Note that the matching $\sigma_0(i) = i$ is the unique NTU stable matching, and is also the unique TU stable matching. To sustain it in the TU game, however, requires transfers. Indeed, $u(i_1) = 0$ and $v(j_2) = 2$ cannot be TU stable payoffs as

$$2 = u(i_1) + v(j_2) < U(i_1, j_2) + V(i_1, j_2) = 3$$

contradicts Definition 4. Intuitively, one needs to compensate agent $i = 1$ in order for him to remain matched with $j = 1$. Hence, even though σ_0 is NTU-stable and TU-stable, transfers between the agents are required to sustain it as TU-stable. Anticipating the definition to follow, this means this matching is not a No-trade matching.

Matching $\sigma_0(i) = i$ is *no-trade stable* when it is TU stable and there are no actual transfers between partners at equilibrium. In other words, Equation (2.1) should hold with $T_i = 0$. That is, $U(i, i) = u(i)$, $V(j, j) = v(j)$, and so:

Definition 6 (No-Trade Matching) *Matching $\sigma_0(i) = i$ is no-trade stable if and only if for all i and j ,*

$$U(i, j) + V(i, j) \leq U(i, i) + V(j, j).$$

Therefore in a no-trade stable matching, two matched individuals would have the opportunity to operate monetary transfers, but they choose not to do so. To put this in different terms, in a no-trade stable matching, spouses are “uncorrupted” because no monetary transfer actually takes place between them, but they are not “incorruptible”, because the rules of the game would allow for it.

3 Cardinal characterizations

We now present simple characterizations of the solution concepts described in Section 2.2.

Our characterizations involve cardinal notions, even for the solutions that are purely ordinal in nature. The point is to characterize all solutions using similar concepts, so it is easier to understand how the solutions differ. It will also help us understand the role of transfers in matching markets.

We need to introduce the following notation:

$$\begin{aligned} R_{ij} &= U(i, i) - U(i, j) \\ S_{ij} &= V(j, j) - V(i, j), \end{aligned}$$

defined for each $i \in M$ and $j \in W$. Note that R_{ij} measures how much i prefers his current partner to j , and S_{ij} measures how much j prefers her current partner to i .

Theorem 7 *Matching $\sigma_0(i) = i$ is:*

(a) *No-trade stable iff*

$$0 \leq R_{ij} + S_{ij} \quad (3.1)$$

(b) *NTU stable iff for all i and j*

$$0 \leq \max(R_{ij}, S_{ij}) \quad (3.2)$$

(c) *TU stable iff there exists $(T_i)_{i \in M \cup W}$ such that for all i and j*

$$T_j - T_i \leq R_{ij} + S_{ij} \quad (3.3)$$

(d) *Ex-ante Pareto efficient iff there exist v_i and $\lambda_i, \mu_j > 0$ such that*

$$v_j - v_i \leq \lambda_i R_{ij} + \mu_j S_{ij} \quad (3.4)$$

(e) *Ex-post Pareto iff there exist v_i and $\lambda_i > 0$ such that*

$$v_j - v_i \leq \lambda_i \max(R_{ij}, S_{ij}). \quad (3.5)$$

Observe that (3.4) and (3.5) are ‘‘Afriat inequalities,’’ using the terminology in revealed preference theory.

As a consequence of the previous characterizations, it is straightforward to list the chains of implications between the various solution concepts.

Theorem 8 (i) *The two following chains of implications always hold:*

– *No-trade Stable implies TU Stable implies Ex-ante Pareto implies Ex-post Pareto, and*

– *No-trade Stable implies NTU stable implies Ex-post Pareto.*

(ii) *Assume that there are two agents on each side of the market. Then two additional implications hold:*

– *Ex-Post Pareto implies (and thus is equivalent to) Ex-Ante Pareto, and*

Figure 1: Summary of the implications in Theorem 8, part (ii) with two agents on each side of the market.

– *NTU stable implies Ex-Ante Pareto.*

Any further implication which does not logically follow from those written is false. See Figure (1).

(iii) Assume that there are at least three agents on each side of the market. Then any implication that does not logically follow from the ones stated in part (i) of Theorem 7 above are false. See Figure (2).

The implications in Theorem 8 are illustrated in Figures (1) and (2).

The proof of Theorem 8 is given in the Appendix. It relies on the following counterexamples.

Example 9 Consider

$$U = \begin{pmatrix} 0 & -2 \\ 1 & 0 \end{pmatrix} \text{ and } V = \begin{pmatrix} 0 & -2 \\ 1 & 0 \end{pmatrix} \quad (3.6)$$

Then σ_0 is TU stable, but not NTU stable, and not No-trade stable.

Example 10 Consider

$$U = \begin{pmatrix} 0 & 2 & -1 \\ -1 & 0 & 2 \\ 2 & -1 & 0 \end{pmatrix}, \quad V = \begin{pmatrix} 0 & -1 & 2 \\ 2 & 0 & -1 \\ -1 & 2 & 0 \end{pmatrix}$$

Then σ_0 is NTU stable (hence Ex-Post Pareto efficient). But it is not Ex-Ante Pareto efficient (hence neither No-trade stable nor TU stable). Indeed consider the fair lottery over the 6 existing pure assignments. Under this lottery, each agent achieves a payoff of $1/3$, hence this lottery is ex-ante preferred by each agent to σ_0 .

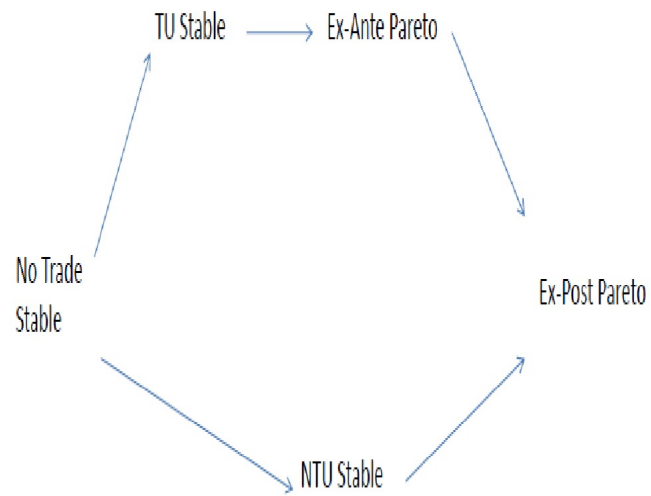

Figure 2: Summary of the implication in Theorem 8, part (iii) with three agents or more on each side of the market.

Example 11 *Consider now*

$$U = \begin{pmatrix} 0 & 1 \\ -2 & 0 \end{pmatrix} \text{ and } V = \begin{pmatrix} 0 & 1 \\ 3 & 0 \end{pmatrix} \quad (3.7)$$

Then σ_0 is ex-ante Pareto efficient, and it is ex-post Pareto efficient, but it is not TU stable, and it is not NTU stable. Ex-ante Pareto efficiency follows from $\lambda_i = 5$, $\mu_j = 1$ and $v_2 = 2$, $v_1 = 1$. Ex-post Pareto efficiency is clear. It is easily seen that σ_0 is not TU stable. It is also clear that the matching is not NTU stable, as $i = 1$, $j = 2$ form a blocking pair.

4 NTU Stability and No-trade matchings

As we explained above, we use no-trade stability to shed light on the role of transfers. Given a stable NTU matching, one may ask if there is a cardinal representation of the agents' utility such that the stable matching is no-trade stable.

As we shall see, the answer is yes if we are allowed to tailor the cardinal representation to the given stable matching. If we instead want a representation that works for all stable matchings in the market, we shall resort to a regularity condition: that the matchings be isolated.

Finally, some statements in Theorem 7 involve the rescaling of utilities: they show how optimality can be understood through the existence of *weights* on the agents that satisfy certain properties. We can similarly imagine finding, not an arbitrary cardinal representation of preferences, but a restricted rescaling of utilities that captures the role of transfers. That is to say, a rescaling of utilities that ensures that the matching is no-trade stable. We shall present an example to the effect that such a rescaling is not possible.

4.1 Linking models with and without transfers

Our first question is whether for a given NTU stable matching, there is a cardinal representation of preferences under which the same matching is No-trade stable. The answer is yes.

Theorem 12 *Let (M, W, P) be an ordinal matching market. If σ is a stable matching, then there is a cardinal representation of P such that σ is a no-trade matching in the corresponding cardinal market.*

It is natural to try to strengthen this result in two directions. First, we could expect to choose the cardinal representation of preferences as a linear rescaling of a given cardinal representation of the preferences. Given what we know about optimality being characterized by choosing appropriate utility weights, it makes sense to ask whether any stable matching can be obtained as a No-Trade Matching if one only weights agents in the right way. Namely:

Problem 13 *Is it the case that matching σ_0 is NTU stable if and only if there is $\lambda_i, \mu_j > 0$ such that*

$$0 \leq \lambda_i R_{ij} + \mu_j S_{ij}?$$

After all, transfers favor some agents over others, and utility weights play a similar role. Our next example shows that this is impossible. It exhibits a stable matching that is not No-Trade for any choice of utility weights.

Example 14 *Consider a marriage market defined as follows. The sets of men and women are: $M = \{m_1, m_2, m_3, m_4\}$ and $W = \{w_1, w_2, w_3, w_4\}$. Agents' preferences are defined through the following utility functions:*

$$U = \begin{pmatrix} 1.01 & 0 & \underline{1/2} & -1 \\ 0 & 1 & -1 & \underline{1/2} \\ \underline{1/2} & 1/5 & 1/3 & 1/4 \\ 1/5 & \underline{1/2} & 1/3 & 1/4 \end{pmatrix}, \quad V = \begin{pmatrix} 0 & 1 & \underline{1/2} & -1 \\ 1 & 0 & -1 & \underline{1/2} \\ \underline{1/2} & 1/5 & 1/3 & 1/4 \\ 1/5 & \underline{1/2} & 1/3 & 1/4 \end{pmatrix}$$

The unique stable matching is underlined. Uniqueness is readily verified by running the Gale-Shapley algorithm. So $u_i = v_j = 1/2$ for all i and j . Yet it is shown in the appendix that there are no $\lambda_i, \mu_j > 0$ such that for all (i, j) ,

$$\lambda_i(u_i - U_{ij}) + \mu_j(v_j - V_{ij}) \geq 0.$$

Example 14 has the following implication (which also follows from Example 5).

Corollary 1 *There are cardinal matching markets that do not possess a no-trade matchings.*

Given Example 14, it is clear that No-Trade can only be achieved by appropriate choice of agents' utility functions. Our next question deals with the existence of cardinal utilities such that the set of No-trade matchings and

NTU stable matchings will coincide for *all* stable matchings in a market. We show that if the stable matchings are isolated then one can choose cardinal utilities such that all stable matchings are No-Trade.

Let $S(P)$ denote the set of all stable matchings. A matching $\sigma \in S(P)$ is *isolated* if $\mu'(a) \neq \sigma(a)$ for all $a \in M \cup W$ and $\mu' \in S(P) \setminus \{\sigma\}$.

Theorem 15 *There is a representation (U, V) of P such that for all $\sigma \in S(P)$, if μ is isolated then μ is no trade stable for (U, V) .*

The question whether the conclusion holds without the assumption that the matching is isolated remains open to investigation.

4.2 Price of Anarchy

The logic of the previous subsection can be pushed further, to obtain a “Price of Anarchy,” in the spirit of the recent literature in computer science (Roughgarden (2005)). We *quantify* the cost in social surplus (sum of agents’ utilities) that results from NTU stability: we can think of this cost as an efficiency gap inherent in the notion of stable matching. The result is that the gap can be arbitrarily large, and that it grows “super exponentially” in the size of the market (i.e. it grows at a faster rate than n^g , for any g , where n is the size of the market).

Let Δ^ϵ denote the subset of the simplex in \mathbf{R}^{2n} in which every component is at least ϵ : $\Delta^\epsilon = \{((\alpha(i))_{i \in M}, (\beta(j))_{j \in W}) : \forall i \in M \alpha(i) \geq \epsilon, \forall j \in W, \beta(j) \geq \epsilon\}$. Let $S(M, W, U, V)$ denote the set of stable matchings in the cardinal matching market (M, W, U, V) . In the statement of the results below, we write the matchings in $S(M, W, U, V)$ as fractional matchings π in which every entry in π is either 0 or 1.

Proposition 16 *For every $\epsilon > 0$, n , g , and $K > 0$ There is a cardinal marriage market (M, W, U, V) , with n men and women, and where utilities U and V are bounded by K such that*

$$\frac{\min_{(\alpha, \beta) \in \Delta^\epsilon} \left\{ \begin{array}{l} \max_{\pi \in \Pi} \sum_{i=1}^n \alpha(i) \sum_{j'=1}^n \pi_{i,j'} U(i, j') \\ + \sum_{j=1}^n \beta(j) \sum_{i'=1}^n \pi_{i',j} V(i', j) \end{array} \right\}}{\max_{(\alpha, \beta) \in \Delta^\epsilon} \left\{ \begin{array}{l} \max_{\pi \in S(M, W, U, V)} \sum_{i=1}^n \alpha(i) \sum_{j'=1}^n \pi_{i,j'} U(i, j') \\ + \sum_{j=1}^n \beta(j) \sum_{i'=1}^n \pi_{i',j} V(i', j) \end{array} \right\}} \text{ is } \Omega(n^g K)$$

Proposition 16 shows that the gap in the sum of utilities, between the maximizing (probabilistic) matchings, and the stable matchings, is large and grows with the size of the market at a rate that is arbitrarily large. Moreover, the gap is large regardless of how one weighs agents' utilities.

Of course, the interpretation of Proposition 16 is not completely straightforward. It does not seem right to compare the sum of utilities in a model in which transfers are not allowed with the sum of utilities in the TU model.³ Nevertheless, we hope that Proposition 16 sheds additional light on the role of transfers in matching markets.

A Appendix: Proofs

A.1 Proof of Theorem 7

Proof. (i) (a) Characterization (3.2) follows directly from the definition.

(b) For characterization of TU stability in terms of (3.3), recall that according to the definition, matching $\sigma_0(i) = i$ is TU Stable if there are vectors $u(i)$ and $v(j)$ such that for each i and j ,

$$u(i) + v(j) \geq U(i, j) + V(i, j)$$

with equality for $i = j$. Hence, there exists a monetary transfer T_i (of either sign) from man i to woman i at equilibrium given by

$$T_i = u(i) - U(i, i) = V(i, i) - v(i).$$

The stability condition rewrites as $T_j - T_i \leq R_{ij} + S_{ij}$, thus, one is led to characterization (3.3).

(c) For characterization of Ex-post Pareto efficient matchings in terms of (3.5), assume σ_0 is Ex-post Pareto efficient, and let

$$Q_{ij} = \max(R_{ij}, S_{ij}),$$

so that by definition, matrix Q_{ij} satisfies “**cyclical consistency**”: for any cycle $i_1, \dots, i_{p+1} = i_1$,

$$\forall k, Q_{i_k i_{k+1}} \leq 0 \text{ implies } \forall k, Q_{i_k i_{k+1}} = 0, \tag{A.1}$$

By the Linear Programming proof of Afriat’s theorem in Fostel, Scarf, and Todd (2004)⁴, see implication (i) implies (ii) in Ekeland and Galichon (2012), there are scalars $\lambda_i > 0$ and v_i such that (3.5) holds.

(d) For characterization of Ex-ante Pareto efficient matchings in terms of (3.4), the proof is an extension of the proof by Fostel, Scarf, and Todd (2004), which give in full. Assume σ_0 is Ex-ante efficient. Then the Linear

⁴The link between Afriat’s theorem and the characterization of efficiency in the housing problem was first made in Ekeland and Galichon (2012).

Programming problem

$$\begin{aligned}
& \max \sum_i x_i + \sum_j y_j \\
& \text{s.t.} \\
& x_i = - \sum_j \pi_{ij} R_{ij} \text{ and } y_j = - \sum_i \pi_{ij} S_{ij} \\
& \sum_k \pi_{ik} = \sum_k \pi_{ki} \text{ and } \sum_k \pi_{ik} = 1 \\
& x_i \geq 0, y_j \geq 0, \pi_{ij} \geq 0.
\end{aligned}$$

is feasible and its value is zero. Thus it coincides with the value of its dual, which is

$$\begin{aligned}
& \min - \sum_i \phi_i \\
& \text{s.t.} \\
& v_j - v_i \leq \lambda_i R_{ij} + \mu_j S_{ij} + \phi_i \\
& \lambda_i \geq 1 \text{ and } \mu_j \geq 1
\end{aligned}$$

where variables λ_i , μ_j , v_i and ϕ_i in the dual problem are the Lagrange multipliers associated to the four constraints in the primal problem, and variables π_{ij} , x_i , and y_j in the primal problem are the Lagrange multipliers associated to the three constraints in the dual problem. Hence the dual program is feasible, and there exist vectors λ , μ , and ϕ , such that

$$\begin{aligned}
v_j - v_i &\leq \lambda_i R_{ij} + \mu_j S_{ij} + \phi_i & (\text{A.2}) \\
\lambda_i &\geq 1 \text{ and } \mu_j \geq 1 \\
\sum_i \phi_i &= 0
\end{aligned}$$

but setting $j = i$ in inequality (A.2) implies (because $R_{ii} = S_{ii} = 0$) that $\phi_i \geq 0$, hence as $\sum_i \phi_i = 0$, thus $\phi_i = 0$. Therefore it exist vectors $\lambda_i > 0$ and $\mu_j > 0$, such that

$$v_j - v_i \leq \lambda_i R_{ij} + \mu_j S_{ij}$$

QED.

(e) Characterization of No-trade stable matchings as in (3.1) follows directly from the definition. ■

A.2 Proof of Theorem 8

Proof. (i) No trade stable implies TU Stable is obtained by taking with $T_i = 0$ in (3.3).

TU Stable implies Ex-ante Pareto is obtained by taking $v_i = T_i$ and $\lambda_i = \mu_j = 1$ in (3.4).

To show that Ex-ante Pareto implies Ex-post Pareto, assume there exist v_i and $\lambda_i, \mu_j > 0$ such that $v_j - v_i \leq \lambda_i R_{ij} + \mu_j S_{ij}$. Now assume $\max(R_{ij}, S_{ij}) \leq 0$. Then $v_j - v_i \leq 0$, and the same implication holds with strict inequalities. By implication (iii) implies (ii) in Ekeland and Galichon (2012), there exist scalars v'_i and λ'_i such that $v'_j - v'_i \leq \lambda'_i \max(R_{ij}, S_{ij})$.

No-trade stable implies NTU stable follows from $R_{ij} + S_{ij} \leq 2 \max(R_{ij}, S_{ij})$.

NTU Stable implies Ex-post Pareto is obtained by taking $\lambda_i = 1$ and $v_i = 0$ in (3.5).

Part (i) of the result is proved using a series of counterexample, which for the most part only require two agents (one can incorporate a third neutral agents, which has zero utility regardless of the outcome).

We show point (iii) before point (ii). In order to show (iii), it is enough to show the following claims, proved in Examples 9 to 11:

- TU Stable does not imply NTU Stable – cf. example 9
- NTU Stable does not imply Ex-Ante Pareto – cf. example 10
- Ex-Ante Pareto does not imply TU Stable – cf. example 11
- Ex-Ante Pareto does not imply NTU Stable – cf. example 11
- Ex-Post Pareto does not imply Ex-Ante Pareto – cf. example 10
- Ex-Post Pareto does not imply NTU stable – cf. example 11.

To prove part (ii), we note that in the proof of part (i), the only instance where we needed three agents was to disprove that NTU stable implies Ex-Ante Pareto efficient and to disprove that Ex-Post Pareto efficient implies Ex-Ante Pareto efficient. We will show that these implications actually hold when there are only two agents. Indeed, when there are two agents, σ_0 is Ex-Ante Pareto efficient if there are positive scalars $\lambda_1, \lambda_2, \mu_1$ and μ_2 such that

$$0 \leq \lambda_1 R_{12} + \lambda_2 R_{21} + \mu_1 S_{12} + \mu_2 S_{21}$$

which is equivalent to

$$0 \leq \max(R_{12}, R_{21}, S_{12}, S_{21}). \quad (\text{A.3})$$

Therefore, if σ_0 is Ex-Post Pareto efficient, then $v_j - v_i \leq \lambda_i \max(R_{ij}, S_{ij})$. But either $v_1 - v_2$ or $v_2 - v_1$ is nonnegative, thus (A.3) holds, and Ex-Post Pareto efficient implies Ex-Ante Pareto efficient. ■

A.3 Proof of Theorem 12

Assume $\mu_0(i) = i$ (this is w.l.o.g. as can always relabel individuals). Take $R_{ij} = U(i, j) - U(i, i)$ and $S_{ij} = V(i, j) - V(j, j)$. μ_0 is Stable iff $\min(R_{ij}, S_{ij}) \leq 0$ for all i and j , with strict inequality for $j \neq i$.

One has for $i \neq j$, as $t \rightarrow \infty$

$$\frac{1}{t} \log(e^{-tR_{ij}} + e^{-tS_{ij}}) \rightarrow \min(R_{ij}, S_{ij})$$

hence for t large enough and $i \neq j$,

$$\frac{-1}{t} \log(e^{-tR_{ij}} + e^{-tS_{ij}}) < 0$$

that is

$$e^{-tR_{ij}} + e^{-tS_{ij}} > 1.$$

Take

$$t > \max_{i \neq j} \left(\left| \frac{\log 2}{R_{ij}} \right|, \left| \frac{\log 2}{S_{ij}} \right| \right)$$

and consider

$$\begin{aligned} \bar{U}(i, j) &= \frac{1}{2} - e^{-tR_{ij}} \text{ for } i \neq j \\ \bar{U}(i, i) &= 0 \end{aligned}$$

one has:

- $\bar{U}(i, j) > 0$ if and only if $\frac{1}{2} > e^{-tR_{ij}}$ that is $-\log 2 > -tR_{ij}$ that is $tR_{ij} > \log 2$ hence $R_{ij} > 0$.
- $\bar{U}(i, j) < 0$ if and only if $tR_{ij} < \log 2$ hence $R_{ij} < 0$.

With a similar construction for $\bar{V}(i, j)$, one has

$$\bar{U}(i, j) + \bar{V}(i, j) \leq 0 = \bar{U}(i, i) + \bar{V}(j, j).$$

Thus μ_0 is a No-Trade Matching associated to utilities \bar{U} and \bar{V} . ■

A.4 Claim in Example 14

The problem is to find $x \gg 0$ such that $A \cdot x \geq 0$. We introduce the matrix B such that the i 'th row of B is the vector $e_i = (0, \dots, 1, \dots, 0)$ with a 1 only in entry i . Then we want to find a vector $x \in \mathbf{R}^n$ such that $A \cdot x \geq 0$ and $B \cdot x \gg 0$. By Motzkin's Theorem of the Alternative, such a vector x exists iff there is no (y, z) , with $z > 0$ (meaning $z \geq 0$ and $z \neq 0$) such that

$$y \cdot A + z \cdot B = 0.$$

$$\begin{array}{cccc|cccc} i & i' & i_0 & i_1 & j & j' & j_0 & j_1 \\ \hline j & j' & \underline{j} & \underline{w}' & i' & i & \underline{i} & \underline{i}' \\ \hline \underline{j_0} & \underline{j_1} & \underline{j_0} & \underline{j_0} & \underline{i_0} & \underline{i_1} & i_0 & i_0 \\ \hline \underline{j}' & \underline{j} & \underline{j_1} & \underline{j_1} & i & i' & i_1 & i_1 \\ \hline j_1 & j_0 & j' & j & i_1 & i_0 & i' & i \end{array}$$

Utilities are:

$$\begin{array}{cccc|cccc} i & i' & i_0 & i_1 & j & j' & j_0 & j_1 \\ \hline 1 + \delta & 1 & 1/2 & 1/2 & 1 & 1 & 1/2 & 1/2 \\ \hline 1/2 & 1/2 & 1/3 & 1/3 & 1/2 & 1/2 & 1/3 & 1/3 \\ \hline 0 & 0 & 1/4 & 1/4 & 0 & 0 & 1/4 & 1/4 \\ \hline -1 & -1 & 1/5 & 1/5 & -1 & -1 & 1/5 & 1/5 \end{array}$$

The upper 4 rows of A are:

$$\begin{array}{c|cccccccc} & i & i' & i_0 & i_1 & j & j' & j_0 & j_1 \\ \hline i, j & 1/2 - (1 + \delta) & 0 & 0 & 0 & 1/2 & 0 & 0 & 0 \\ i, j' & 1/2 & 0 & 0 & 0 & 0 & 1/2 - 1 & & \\ i', j & 0 & 1/2 & 0 & 0 & -1/2 & 0 & 0 & 0 \\ i', j' & 0 & -1/2 & 0 & 0 & 0 & 1/2 & 0 & 0 \end{array}$$

So the sum of the first four rows of A is $(-\delta, 0, 0, 0, 0, 0, 0, 0, 0)$.

Notice that we have other rows: for example the row corresponding to (i, j_1) is:

$$\begin{array}{c|cccccccc} & i & i' & i_0 & i_1 & j & j' & j_0 & j_1 \\ \hline i, j_1 & 1/2 + 1 & 0 & 0 & 0 & 0 & 0 & 0 & 1/2 - 1/5, \end{array}$$

but these rows will get weight zero in the linear combination below.

So $y = (1, 1, 1, 1, 0, \dots, 0)$ and $z = (\delta, 0, \dots, 0)$ exhibit a solution to the alternative system as

$$y \cdot A + z \cdot B = (-\delta, 0, 0, 0, 0, 0, 0, 0) + \delta(1, 0, \dots, 0) = 0$$

■

A.5 Proof of Theorem 15.

Let $S(P)$ be the set of stable matchings in the ordinal matching market (M, W, P) . Suppose that there are N stable matchings, and enumerate them, so $S(P) = \{\mu^1, \dots, \mu^K\}$.

To prove the proposition we first establish some simple lemmas.

Lemma 2 *For any $i \in M$ and $j \in W$,*

$$|\{k : j >_i \mu^k(i)\}| + |\{k : i >_j \mu^k(j)\}| \leq K - |\{k : j = \mu^k(i)\}|$$

Proof. Let $j >_i \mu^k(i)$; then for μ^k to be stable we need that $\mu^k(j) >_j i$. So $|\{k : j >_i \mu^k(i)\}| \leq |\{k : \mu^k(j) >_j i\}|$.

Then,

$$\begin{aligned} |\{k : i >_j \mu^k(j)\}| &= K - |\{k : \mu^k(j) \geq_j i\}| \\ &\leq K - |\{k : j >_i \mu^k(i)\}| - |\{k : j = \mu^k(i)\}|, \end{aligned}$$

where the last inequality follows from the previous paragraph and the fact that preferences $>_j$ are strict. ■

Let $\hat{U}(i, j) = |\{k : j \geq_i \mu^k(i)\}|$ and $\hat{V}(i, j) = |\{k : i >_j \mu^k(j)\}|$. By the previous lemma, $\hat{U}(i, j) + \hat{V}(i, j) \leq K$ for all i and j .

Lemma 3 *If μ is an isolated stable matching, and $i, \hat{i} \in M$, then $\mu(i) >_i \mu'(i)$ iff $\mu(\hat{i}) >_{\hat{i}} \mu'(\hat{i})$.*

Proof. Suppose (reasoning by contradiction) that $\mu(i) >_i \mu'(i)$ while $\mu'(\hat{i}) \geq_{\hat{i}} \mu(\hat{i})$. Since μ is isolated and preferences are strict, we have $\mu'(\hat{i}) >_{\hat{i}} \mu(\hat{i})$. Now let $\hat{\mu} = \mu \vee \mu'$, using the join operator in the lattice of stable matchings (see Roth and Sotomayor (1990)). Then $\hat{\mu}(i) = \mu(i)$ and $\hat{\mu}(\hat{i}) = \mu'(\hat{i})$. So $\hat{\mu} \in S(P)$, $\hat{\mu}(i) = \mu(i)$, and $\hat{\mu} \neq \mu$; a contradiction of the hypothesis that μ is isolated. ■

Lemma 4 *If μ is an isolated stable matching then*

$$\hat{U}(i, \mu(i)) + \hat{V}(\mu(j), j) = K.$$

Proof. We prove that

$$\{k : \mu \neq \mu^k \text{ and } \mu(i) \geq_i \mu^k(i)\} = \{k : \mu \neq \mu^k \text{ and } \mu^k(j) \geq_j \mu(j)\}.$$

The lemma follows then because

$$\begin{aligned} \hat{U}(i, \mu(i)) + \hat{V}(\mu(j), j) &= |\{n : \mu(i) \geq_i \mu^k(i)\}| + |\{k : \mu^k(j) >_j \mu(j)\}| \\ &= 1 + |\{k : \mu \neq \mu^k \text{ and } \mu(i) \geq_i \mu^k(i)\}| \\ &\quad + (K - |\{k : \mu \neq \mu^k \text{ and } \mu^k(j) \geq_j \mu(j)\}| - 1). \end{aligned}$$

Let $\mu(i) \geq_i \mu^k(i)$ and let $i = \mu(j)$. Since $\mu \neq \mu^k$ is isolated and preferences are strict, $\mu(i) >_i \mu^k(i)$. Then by Lemma 3, $\mu(i) >_i \mu^k(i)$; so $j = \mu(i)$ implies that $\mu^k(j) >_j \mu(j)$. Similarly, if $\mu^k(j) >_j \mu(j)$ then $\mu(i) >_i \mu^k(i)$. So $\mu(i) >_i \mu^k(i)$. ■

We are now in a position to prove the proposition.

Define a representation U and V of P as follows. Fix δ such that $0 < \delta < 1/2$. Let $U(i, j) = \hat{U}(i, j)$ and $V(i, j) = \hat{V}(i, j)$ if there is $\mu \in S(P)$ such that $j = \mu(i)$. Otherwise, if j is worse than i 's partner in any stable matching, let $U(i, j) < 0$ (and chosen to respect representation of P); and if there is $\mu \in S(P)$ such that $j >_i \mu(i)$, let μ^0 be the best such matching for i , and choose $U(i, j)$ such that $U(i, j) - U(i, \mu^0(i)) < \delta$. Choose V similarly.

Let μ be an isolated matching. Fix a pair (i, j) and suppose, wlog that $u_\mu(i) - U(i, j) < 0$ and $v_\mu(i) - V(i, j) \geq 0$ (if $u_\mu(i) - U(i, j) \geq 0$ and $v_\mu(i) - V(i, j) \geq 0$ then there is nothing to prove; and they cannot both be < 0 or (i, j) would constitute a blocking pair).

First, if i and j are matched in some matching $\mu' \in S(P)$ then $u_\mu(i) - U(i, j) + v_\mu(i) - V(i, j) = u_\mu(i) - \hat{U}(i, j) + v_\mu(i) - \hat{V}(i, j)$ so it follows that $u_\mu(i) - U(i, j) + v_\mu(i) - V(i, j) \geq 0$ by Lemmas 2, 4, and the definition of $\hat{U}(i, j)$ and $\hat{V}(i, j)$.

Second, let us assume that i and j are not matched in any matching in $S(P)$. Since $u_\mu(i) - U(i, j) < 0$ we know that there is a matching that is worse for i than j . Let μ^0 be such that $j >_i \mu^0(i)$ implies that $\mu^0(i) \geq_i \mu^0(i)$. Thus $u_{\mu^0}(i) - U(i, j) > -\delta$ by definition of $U(i, j)$. Since $j >_i \mu^0(i)$, we also have $\mu^0(j) >_j i$, or μ^0 would not be stable. Then, letting μ^1 be the

best matching in $S(P)$ for j , out of those that are worse than i , we have $v_{\mu^0}(j) - V(i, j) = v_{\mu^0}(j) - v_{\mu^1}(j) + v_{\mu^1}(j) - V(i, j) > 1 - \delta$, as $\mu^0(j) >_j \mu^1(j)$ implies that $v_{\mu^0}(j) - v_{\mu^1}(j) \geq 1$ and the definition of $V(i, j)$ implies that $v_{\mu^1}(j) - V(i, j) > -\delta$.

Finally,

$$\begin{aligned}
u_{\mu}(i) - U(i, j) + v_{\mu}(i) - V(i, j) &= u_{\mu}(i) - u_{\mu^0}(i) + u_{\mu^0}(i) - U(i, j) \\
&\quad + v_{\mu}(i) - v_{\mu^0}(j) + v_{\mu^0}(j) - V(i, j) \\
&= (u_{\mu}(i) - u_{\mu^0}(i) + v_{\mu}(i) - v_{\mu^0}(j)) \\
&\quad + (u_{\mu^0}(i) - U(i, j)) + (v_{\mu^0}(j) - V(i, j)) \\
&\geq 0 + (-\delta) + (1 - \delta) > 0,
\end{aligned}$$

where the first inequality follows from the remarks in the previous paragraphs, and from the fact that $K = u_{\mu}(i) + v_{\mu}(i) \geq u_{\mu^0}(i) + v_{\mu^0}(j)$ by Lemmas 2 and 4. The second inequality follows because $\delta < 1/2$. This proves the proposition.

A.6 Proof of Proposition 16

Let n be an even positive number. Let (M, W, U, V) be a marriage market with n men and n women, defined as follows. The agents ordinal preferences are defined in the following tables:

i_1	i_2	i_3	\cdots	i_{n-2}	i_{n-1}	i_n
j_1	j_2	j_3	\cdots	j_{n-2}	j_{n-1}	j_{n-1}
j_2	j_3	j_4	\cdots	j_{n-1}	j_1	j_1
j_3	j_4	j_5	\cdots	j_{n-2}	j_1	j_2
\vdots						
$j_{n/2}$	$j_{n/2+1}$	$j_{n/2+1}$	\cdots	$j_{n/2-2}$	$j_{n/2-1}$	$j_{n/2-1}$
						j_n
\vdots						
j_{n-1}	j_n	j_1	\cdots			
j_n	j_1	j_2	\cdots	j_{n-3}	j_{n-2}	

The table means that j_1 is the most preferred partner for i_1 , followed by j_2 , and so on. The women's' preferences are as follows.

j_1	j_2	j_3	\cdots	j_{n-2}	j_{n-1}	j_n
i_2	i_3	i_4	\cdots	i_{n-1}	i_1	i_1
i_3	i_4	i_5	\cdots	i_{n-1}	i_2	i_2
\vdots						
$i_{n/2}$	$i_{n/2+1}$	$i_{n/2+2}$	\cdots	$i_{n/2-2}$	$i_{n/2-1}$	$i_{n/2-1}$
$i_{n/2+1}$	$i_{n/2+2}$	$i_{n/2+3}$	\cdots	$i_{n/2}$	$i_{n/2}$	
\vdots						
i_{n-1}	i_n	i_1	\cdots	i_{n-4}	i_{n-3}	
i_n	i_1	i_2	\cdots	i_{n-3}	i_{n-1}	
i_1	i_2	i_3	\cdots	i_{n-2}	i_n	
i_1	i_2	i_3	\cdots	i_{n-2}	i_{n-1}	i_n

It is a routine matter to verify that there is a unique stable matching in this market. It has i_1 matched to $j_{n/2}$, i_2 matched to $j_{n/2+1}$, and so on, until we obtain that i_{n-1} is matched to $j_{n/2-1}$. We have i_n matched to j_n . (The logic of this example is that i_n creates cycles in the man-proposing algorithm which pushes the men down in their proposals until reaching the matching in the “middle” of their preferences; j_n plays the same role in the woman proposing version of the algorithm).

Define agents' cardinal preferences as follows. Let

$$U(i, j) = [n - r_m(w)] \frac{1}{n^g} + \max\{0, n - 1 - r_i(j)\} \left(K - \frac{n - 1}{n^g}\right),$$

where $r_i(j)$ is the rank of woman j in i ' preferences. Similarly define $V(i, j)$, replacing $r_i(j)$ with $r_j(i)$. Then, given the preferences defined above, the agents utilities at the unique stable matching satisfy:

$$u(i_l) = v(j_l) = \frac{1}{2n^{g-1}}, l = 1, \dots, n - 1 \text{ and } u(i_n) = v(j_n) = (n/2 - 1) \frac{1}{n^g}.$$

So that the sum of all agents utilities at the unique stable matching is:

$$2(n - 1) \left(\frac{1}{2n^{g-1}}\right) + 2(n/2 - 1) \frac{1}{n^g},$$

and agents' weighted sum of utilities is at most

$$\max\left\{\frac{1}{2n^{g-1}}, (n/2 - 1)\frac{1}{n^g}\right\}.$$

Consider the matchings $\mu^*(i_l) = j_l, l = 1, \dots, n$, and $\hat{\mu}(j_1) = i_2, \dots, \hat{\mu}(j_{n-2}) = i_{n-1}, \hat{\mu}(j_{n-1}) = i_1, \hat{\mu}(j_n) = i_n$. Let π be the random matching that results from choosing μ^* and $\hat{\mu}$ with equal probability. Then, for all $i \neq i_n$ and $j \neq j_n$ we have that

$$\sum_{j'} \pi_{i,j'} U(i, j') = \sum_{i'} \pi_{j,i'} V(i', j) = K/2,$$

while

$$\sum_{j'} \pi_{i_n,j'} U(i_n, j') = \sum_{i'} \pi_{j,i'} V(i', j_n) = (n/2 - 1)\frac{1}{n^3}.$$

Then

$$\sum_{i \in M} \alpha(i) \sum_{j' \in W} \pi_{i,j'} U(i, j') + \sum_{j \in W} \beta(j) \sum_{i' \in M} \pi_{j,i'} V(i', j) \geq \epsilon n K/2.$$

So, regardless of the values of α and β in Δ^ϵ , the fraction

$$\frac{\sum_{i \in M} \alpha(i) \sum_{j' \in W} \pi_{i,j'} U(i, j') + \sum_{j \in W} \beta(j) \sum_{i' \in M} \pi_{j,i'} V(i', j)}{\sum_{i \in M} \alpha(i) u(i) + \sum_{j \in W} \beta(j) v(j)}$$

is bounded below by

$$\frac{\epsilon n K/2}{\max\left\{\frac{1}{2n^{g-1}}, (n/2 - 1)\frac{1}{n^g}\right\}},$$

which is $\Omega(Kn^g)$. ■
